Quiz 4

✓

6/6 questions correct

Quiz passed!

✔ 1.

Consider the space shuttle data `?shuttle` in the `MASS` library. Consider modeling the use of the autolander as the outcome (variable name `use`). Fit a logistic regression model with autolander (variable auto) use (labeled as "auto" 1) versus not (0) as predicted by wind sign (variable wind). Give the estimated odds ratio for autolander use comparing head winds, labeled as "head" in the variable headwind (numerator) to tail winds (denominator).

○ -0.031

○ 0.969

Well done!

```
library(MASS)
data(shuttle)
## Make our own variables just for illustration
shuttle$auto <- 1 * (shuttle$use == "auto")
shuttle$headwind <- 1 * (shuttle$wind == "head")
fit <- glm(auto ~ headwind, data = shuttle, family = binomial)
exp(coef(fit))
```

```
## (Intercept)      headwind
##      1.3273      0.9687
```

```
## Another way without redifing variables
fit <- glm(relevel(use, "noauto") ~ relevel(wind, "tail
"), data = shuttle, family = binomial)
exp(coef(fit))
```

```
##                 (Intercept) relevel(wind, "tail")head
##                      1.3273                    0.9687
```

- ○ 0.031

- ○ 1.327

✔ **2.**

Consider the previous problem. Give the estimated odds ratio for autolander use comparing head winds (numerator) to tail winds (denominator) adjusting for wind strength from the variable magn.

- ○ 1.00

- ○ 0.684

- ○ 0.969

Well done!
The estimate doesn't change with the inclusion of wind strength

```
shuttle$auto <- 1 * (shuttle$use == "auto")
shuttle$headwind <- 1 * (shuttle$wind == "head")
fit <- glm(auto ~ headwind + magn, data = shuttle, fami
ly = binomial)
exp(coef(fit))
```

```
## (Intercept)      headwind  magnMedium       magnOut  mag
nStrong
##       1.4852        0.9685       1.0000        0.6842
0.9376
```

```
## Another way without redifing variables
fit <- glm(relevel(use, "noauto") ~ relevel(wind, "tail
") + magn, data = shuttle,
    family = binomial)
exp(coef(fit))
```

```
##                 (Intercept) relevel(wind, "tail")head
##                      1.4852                     0.9685
##                 magnMedium                     magnOut
##                      1.0000                     0.6842
##                 magnStrong
##                      0.9376
```

○ 1.485

✔ 3.

If you fit a logistic regression model to a binary variable, for example use of
the autolander, then fit a logistic regression model for one minus the outcome
(not using the autolander) what happens to the coefficients?

○ The coefficients reverse their signs.

Well done!
Remember that the coefficients are on the log scale. So changing the
sign changes the numerator and denominator for the exponent.

○ The coefficients change in a non-linear fashion.

○ The coefficients get inverted (one over their previous value).

○ The intercept changes sign, but the other coefficients don't.

✓ 4.

Consider the insect spray data `InsectSprays`. Fit a Poisson model using spray as a factor level. Report the estimated relative rate comapring spray A (numerator) to spray B (denominator).

○ 0.136

○ 0.9457

Well done!

```
fit <- glm(count ~ relevel(spray, "B"), data = InsectSp
rays, family = poisson)
exp(coef(fit))[2]
```

```
## relevel(spray, "B")A
##                0.9457
```

○ -0.056

○ 0.321

✓ 5.

Consider a Poisson glm with an offset, t. So, for example, a model of the form glm(count ~ x + offset(t), family = poisson) where x is a factor variable comparing a treatment (1) to a control (0) and t is the natural log of a monitoring time. What is impact of the coefficient for x if we fit the model glm(count ~ x + offset(t2), family = poisson) where 2 <- log(10) + t? In other words, what happens to the coefficients if we change the units of the offset variable. (Note, adding log(10) on the log scale is multiplying by 10 on the original scale.)

○ The coefficient estimate is divided by 10.

○ The coefficient is subtracted by log(10).

○ The coefficient estimate is unchanged

○ The coefficient estimate is multiplied by 10.

✓ 6.

Consider the data

```
x <- -5:5
y <- c(5.12, 3.93, 2.67, 1.87, 0.52, 0.08, 0.93, 2.05, 2.54, 3
.87, 4.97)
```

Using a knot point at 0, fit a linear model that looks like a hockey stick with two lines meeting at x=0. Include an intercept term, x and the knot point term. What is the estimated slope of the line after 0?

○   -1.024

○   -0.183

○   2.037

○   1.013
